## Least squares estimator

- **Least squares estimator :**

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_K x_K + \varepsilon \quad (1)$$

where

- ▶  $y$  is the (outcome) dependent variable;
  - ▶  $x_1, x_2, \dots, x_K$  is the set of independent variables;
  - ▶  $\varepsilon$  is the error term.
- The dependent variable is explained with the components that vary with the **the dependent variable** and **the error term**.
  - $\beta_0$  is the intercept.
  - $\beta_1, \beta_2, \dots, \beta_K$  are the coefficients (slopes) on  $x_1, x_2, \dots, x_K$ .

## ■ Least squares estimator :

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_K x_K + \varepsilon \quad (1)$$

where

- ▶  $y$  is the (outcome) dependent variable;
  - ▶  $x_1, x_2, \dots, x_K$  is the set of independent variables;
  - ▶  $\varepsilon$  is the error term.
- The dependent variable is explained with the components that vary with the **the dependent variable** and **the error term**.
- $\beta_0$  is the intercept.
- $\beta_1, \beta_2, \dots, \beta_K$  are the coefficients (slopes) on  $x_1, x_2, \dots, x_K$ .

$\beta_1, \beta_2, \dots, \beta_K$  measure the effect of change in  $x_1, x_2, \dots, x_K$  upon the expected value of  $y$  (*ceteris paribus*).

- **Assumption #1:** true DGP (data generating process):

$$\mathbf{y} = \mathbf{X}\beta + \varepsilon. \quad (2)$$

- **Assumption #2:** the expected value of the error term is zero:

$$\mathbb{E}(\varepsilon) = 0, \quad (3)$$

and this implies that  $\mathbb{E}(y) = \mathbf{X}\beta$ .

- **Assumption #3:** Spherical variance-covariance error matrix.

$$\text{var}(\varepsilon) = \mathbb{E}(\varepsilon\varepsilon') = I\sigma^2 \quad (4)$$

. In particular:

- ▶ the variance of the error term equals  $\sigma$ :

$$\text{var}(\varepsilon) = \sigma^2 = \text{var}(y). \quad (5)$$

- ▶ the covariance between any pair of  $\varepsilon_i$  and  $\varepsilon_j$  is zero"

$$\text{cov}(\varepsilon_i, \varepsilon_j) = 0. \quad (6)$$

- **Assumption #4: Exogeneity.** The independent variable are **not random** and therefore they are not correlated with the error term.

$$\mathbb{E}(\mathbf{X}\varepsilon) = 0. \quad (7)$$

- **Assumption #5:** the full rank of matrix of explanatory variables (there is no so-called collinearity):

$$\text{rank}(\mathbf{X}) = K + 1 \leq N. \quad (8)$$

- **Assumption #6 (optional):** the normally distributed error term:

$$\varepsilon \sim \mathcal{N}(0, \sigma^2). \quad (9)$$

### Assumptions of the least squares estimators

Under the assumptions A#1-A#5 of the multiple linear regression model, the least squares estimator  $\hat{\beta}^{OLS}$  has the smallest variance of all linear and unbiased estimators of  $\beta$ .

$\hat{\beta}^{OLS}$  is the Best Linear Unbiased Estimators (BLUE) of  $\beta$ .

- The least squares estimator

$$\hat{\beta}^{OLS} = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{y}. \quad (10)$$

- The variance of the least square estimator

$$\text{Var}(\hat{\beta}^{OLS}) = \sigma^2 (\mathbf{X}'\mathbf{X})^{-1} \quad (11)$$

- If the (optional) assumption about normal distribution of the error term is satisfied then

$$\beta \sim \mathcal{N}(\hat{\beta}^{OLS}, \text{Var}(\hat{\beta}^{OLS})). \quad (12)$$

## Statistical inference

- **Statistical inference** is the process that using sample data allows to deduce properties of an underlying features of population.
- **Statistical inference** consists of:
  - ▶ estimation of underlying parameters,
  - ▶ testing hypotheses.

- Hypothesis testing is a comparison of a conjecture we have about a population to the information contained in a sample of data.
- The hypotheses are formed about economic behavior.
- In statistical inference, the hypotheses are then represented as statements about model parameters.
- General procedures:
  1. A null hypothesis  $\mathcal{H}_0$ ,
  2. An alternative hypothesis  $\mathcal{H}_1$ ,
  3. A test statistic
  4. A rejection region
  5. A conclusion

- Based on **the value of a test statistic** we decide either to reject the null hypothesis or not to reject it.
- **The rejection region** consists of values that are unlikely and that have low probability of occurring when the null hypothesis is true.
- **The rejection region** depends on:
  - ▶ Distribution of test statistics when the null is true.
  - ▶ Alternative hypothesis.
  - ▶ Level of significance.

- **Type I error** is a situation, in which we reject the null hypothesis when it is true.
- **Type II error** is a situation, in which we do not reject the null hypothesis when it is false.
- **Significance level  $\alpha$ :**

$$P(\text{Type I error}) = \alpha. \quad (13)$$

- $\alpha$  is usually **arbitrary** chosen to be 0.01, 0.05 or 0.10

- Standard practice is to use **the probability value (p-value)**. This is the smallest significance level at which the null hypothesis could be rejected.
- Given p-value we do not have to compare test statistics with the corresponding critical value.
- If the p-value is lower than the significance level ( $\alpha$ ) then we are able to reject the null.

## Testing simply hypotheses

- Based on the  $t$  statistics:

$$t = \frac{\hat{\beta}_i^{LS} - \beta_i}{se(\hat{\beta}_i^{LS})} \sim t_{N-(K+1)}. \quad (14)$$

we can consider the following alternative hypotheses:

- $\mathcal{H}_1 : \beta_i \leq c,$
- $\mathcal{H}_1 : \beta_i \neq c,$
- $\mathcal{H}_1 : \beta_i \geq c.$

- Test of significance:**

- ▶ The null  $\mathcal{H}_0 : \beta_i = 0,$
- ▶ The alternative  $\mathcal{H}_1 : \beta_i \neq 0.$
- ▶ t-test statistics:

$$t = \frac{\hat{\beta}_i^{LS}}{se(\hat{\beta}_i^{LS})} \sim t_{N-(K+1)}, \quad (15)$$

which is an inverse of relative standard error.

The null and alternative:

$$\mathcal{H}_0 : \beta_i = c$$

$$\mathcal{H}_1 : \beta_i \geq c$$

The null hypothesis can be rejected if

$$t \geq t_{(1-\alpha, N-(K+1))}$$

The null and alternative:

$$\mathcal{H}_0 : \beta_i = c$$

$$\mathcal{H}_1 : \beta_i \leq c$$

The null hypothesis can be rejected if

$$t \leq t_{(\alpha, N-(K+1))}$$

The null and alternative:

$$\mathcal{H}_0 : \beta_i = c$$

$$\mathcal{H}_1 : \beta_i \neq c$$

The null hypothesis can be rejected if

$$t \leq t_{(\alpha/2, N-(K+1))}$$

$$\text{or } t \geq t_{(1-\alpha/2, N-(K+1))}$$

- A linear combination of parameters:

$$\lambda = c_1\beta_1 + c_2\beta_2 \quad (16)$$

where  $c_1$  and  $c_2$  are some constants.

- Under the assumptions #1-#6 (without normality of the error term) the least square estimators  $\hat{\beta}_1^{LS}$  and  $\hat{\beta}_2^{LS}$  are the best linear unbiased estimators of  $\beta_1$  and  $\beta_2$ .
- Moreover, the  $\hat{\lambda}^{LS} = c_1\hat{\beta}_1^{LS} + c_2\hat{\beta}_2^{LS}$  is also BLUE of  $\lambda$ .
  - ▶ The estimator  $\hat{\lambda}^{LS}$  is unbiased because:

$$\mathbb{E}(\hat{\lambda}^{LS}) = \mathbb{E}(c_1\hat{\beta}_1^{LS}) + \mathbb{E}(c_2\hat{\beta}_2^{LS}) = c_1\mathbb{E}(\hat{\beta}_1^{LS}) + c_2\mathbb{E}(\hat{\beta}_2^{LS}) = c_1\beta_1 + c_2\beta_2 = \lambda. \quad (17)$$

- The variance of the linear combination of the LS estimates:

$$var(\hat{\lambda}) = var(c_1\hat{\beta}_1^{LS} + c_2\hat{\beta}_2^{LS}) \quad (18)$$

$$= c_1var(\hat{\beta}_1^{LS}) + c_2var(\hat{\beta}_2^{LS}) + 2c_1c_2cov(\hat{\beta}_1^{LS}, \hat{\beta}_2^{LS}). \quad (19)$$

therefore we can estimate the variance of the  $\lambda$  by replacing with the (known) estimated variances and covariance.

$$\hat{var}(\hat{\lambda}) = c_1\hat{var}(\hat{\beta}_1^{LS}) + c_2\hat{var}(\hat{\beta}_2^{LS}) + 2c_1c_2\hat{cov}(\hat{\beta}_1^{LS}, \hat{\beta}_2^{LS}) \quad (20)$$

- if the assumption of the error term normality holds or if the sample is large then  $\hat{\lambda}$  have normal distribution:

$$\hat{\lambda} = c_1 \hat{\beta}_1^{LS} + c_2 \hat{\beta}_2^{LS} \sim \mathcal{N}(\lambda, \text{var}(\hat{\lambda})). \quad (21)$$

- The standard t-statistics for the linear combination is:

$$t = \frac{\hat{\lambda} - \lambda}{\sqrt{\text{var}(\hat{\lambda})}} = \frac{\hat{\lambda} - \lambda}{\text{se}(\hat{\lambda})} \sim t_{N-K}. \quad (22)$$

- Based on the above formulation the variety of hypotheses can be tested. The null is typically:

$$\mathcal{H}_0 : \quad \lambda = c_1 \beta_1 + c_2 \beta_2 = \lambda_0, \quad (23)$$

while the possible alternative hypotheses:

$$\mathcal{H}_1 : \quad \lambda = c_1 \beta_1 + c_2 \beta_2 \neq \lambda_0,$$

$$\mathcal{H}_1 : \quad \lambda = c_1 \beta_1 + c_2 \beta_2 \leq \lambda_0,$$

$$\mathcal{H}_1 : \quad \lambda = c_1 \beta_1 + c_2 \beta_2 \geq \lambda_0.$$

## Confidence intervals

- **Point estimate** is a single value of the estimator (mean).
- **Interval estimation** provides a range of values in which the true parameter is likely to fall
- **Interval estimation** allows to account for the precision with which the unknown parameter is estimated. The precision is typically measured with variance.

- Under the assumption of normality of the error term the least squares estimator of  $\hat{\beta}^{LS}$  is:

$$\hat{\beta}^{LS} \sim \mathcal{N}(\beta, \Sigma) \quad (24)$$

where  $\Sigma$  is the variance-covariance of the least squares estimator.

- For illustrative purpose we focus on slope parameter in the simple regression model ( $\hat{\beta}_1^{LS}$ ):

$$\hat{\beta}_1^{LS} \sim \mathcal{N}\left(\beta_1, \frac{\sigma^2}{\sum_i^N (x_i - \bar{x})^2}\right) \quad (25)$$

- A standardized normal random variable can be obtained from  $\hat{\beta}_1^{LS}$  by subtracting its mean and dividing by its standard deviation

$$Z = \frac{\hat{\beta}_1^{LS} - \beta_1}{\sqrt{\sigma^2 \sum_i^N (x_i - \bar{x})^2}} \sim \mathcal{N}(0, 1). \quad (26)$$

- Based on the features of standard normal distribution:

$$P(-1.96 \leq Z \leq 1.96) = .95, \quad (27)$$

- we can substitute  $Z$

$$P \left( -1.96 \leq \frac{\hat{\beta}_1^{LS} - \beta_1}{\sqrt{\sigma^2 \sum_i^N (x_i - \bar{x})^2}} \leq 1.96 \right) = .95, \quad (28)$$

and after manipulations:

$$P \left( \hat{\beta}_1^{LS} - 1.96 \sqrt{\sigma^2 \sum_i^N (x_i - \bar{x})^2} \leq \beta_1 \leq \hat{\beta}_1^{LS} + 1.96 \sqrt{\sigma^2 \sum_i^N (x_i - \bar{x})^2} \right) = .95. \quad (29)$$

- The two end-points  $\hat{\beta}_1^{LS} \pm 1.96 \sqrt{\hat{\sigma}^2 \sum_i^N (x_i - \bar{x})^2}$  provide an interval estimator.
- In repeated sampling 95% of the intervals constructed this way will contain the true value of the parameter  $\beta_1$ .
- This easy derivation of an interval estimator is based on the assumption about normality of the error term and that we know the variance of the error term  $\sigma^2$ .

- In simple regression, replacing  $\sigma^2$  by its estimates  $\hat{\sigma}^2$  produces a random variable  $t$ :

$$t = \frac{\hat{\beta}_1^{LS} - \beta_1}{\sqrt{\hat{\sigma}^2 \sum_i^N (x_i - \bar{x})^2}} = \frac{\hat{\beta}_1^{LS} - \beta_1}{\sqrt{\widehat{var}(\hat{\beta}_1^{LS})}} = \frac{\hat{\beta}_1^{LS} - \beta_1}{se(\hat{\beta}_1^{LS})}. \quad (30)$$

- In multiple regression model, the  $t$  ratio, i.e.  $t = (\hat{\beta}_j^{LS} - \beta_j)/se(\hat{\beta}_j^{LS})$  has a  $t$ -distribution with  $N - (K + 1)$  degrees of freedoms:

$$t \sim t_{N-(K+1)}, \quad (31)$$

where  $K$  is the number of explanatory variables.

- **Critical value** from a  $t$  distribution  $t_c$  can be found as follows:

$$P(t \geq t_c) = P(t \leq -t_c) = \frac{\alpha}{2}, \quad (32)$$

where  $\alpha$  is arbitrary probability (significance level).

- The confidence intervals:

$$P(-t_c \leq t \leq t_c) = 1 - \alpha, \quad (33)$$

and after manipulations (with definition of  $t$  random variable):

$$P(\hat{\beta}_1^{LS} - t_c se(\hat{\beta}_1^{LS}) \leq \beta_1 \leq \hat{\beta}_1^{LS} + t_c se(\hat{\beta}_1^{LS})) = 1 - \alpha. \quad (34)$$

## Testing joint hypotheses

- A null hypothesis with multiple conjectures, expressed with more than one equal sign, is called a **joint hypothesis**.
- [Example ] Wages ( $w$ ) and experience ( $exper$ ):

$$w = \beta_0 + \beta_1 exper + \beta_2 exper^2 + \varepsilon. \quad (35)$$

- ▶ Are wages related to experience?
- ▶ To answer the above question we should test jointly  $\mathcal{H}_0 : \beta_1 = 0$  and  $\mathcal{H}_0 : \beta_2 = 0$ .
- ▶ The joint null is  $\mathcal{H}_0 : \beta_1 = \beta_2 = 0$ .
- ▶ Test of  $\mathcal{H}_0$  is a joint test for whether all two conjectures hold simultaneously.

- **The restricted least square estimator** is obtained by minimizing the sum of squares (SSE) subject to **set of restrictions**, which is a function of the unknown parameters, given the data:

$$SSE(\beta_0, \beta_1, \dots, \beta_K) = \sum_{i=1}^N [y_i - \beta_0 - \beta_1 x_{i1} - \dots - \beta_K x_{iK}]^2$$

subject to                      restrictions.

- Examples of restrictions:
  - ▶  $\beta_1 = \beta_2$ ,
  - ▶  $\beta_1 = 2$ .

- **Wald test** allows to test a set of linear restrictions.
- **The  $\mathcal{F}$ -statistic** determines what constitutes a large reduction or a small reduction in the sum of squared errors:

$$\mathcal{F} = \frac{(SSE_R - SSE_U) / J}{SSE_U / (N - K)}, \quad (36)$$

where:

- ▶  $J$  is the number of restrictions,
  - ▶  $N$  is the number of observations,
  - ▶  $K$  is the number of coefficients in the unrestricted model,
  - ▶  $SSE_R$  is sum of squared error in **restricted** model,
  - ▶  $SSE_U$  is sum of squared error in **unrestricted** model,
- If the null is true then the  $\mathcal{F}$ -statistic has an  $\mathcal{F}$ -distribution with  $J$  numerator degrees of freedom and  $N - K$  denominator degrees of freedom.
  - If the null can be rejected then, the differences in sum of squared errors between **restricted model** ( $SSE_R$ ) and **unrestricted model** ( $SSE_U$ ) become large.
    - ▶ In other words, the imposed restriction significantly reduce the ability of the model to fit the data.
  - The  $\mathcal{F}$ -test can also be used in many application:
    - ▶ Testing economic hypotheses.

- ▶ Testing the significance of the model.
  - ▶ Excluding/including a set of explanatory variables.
- Alternatively, the  $\mathcal{W}$  statistics can be used which is defined as

$$\mathcal{W} = J\mathcal{F}, \quad (37)$$

and  $\mathcal{W}$  is  $\chi^2$  distributed with the  $J$  degrees of freedom.

- Multiple regression model with  $K$  explanatory variable:

$$y = \beta_0 + \beta_1 x_1 + \dots + \beta_k x_k + \varepsilon. \quad (38)$$

- Test of the overall significance of the regression model.** The null hypothesis:

$$\mathcal{H}_0 : \beta_1 = \beta_2 = \dots = \beta_k = 0, \quad (39)$$

while the alternative is that at least one coefficient is different from 0.

- In this test the restricted model:

$$y = \beta_0, \quad (40)$$

which implies that  $SSE_R = SST$ .

- Thus, the  $\mathcal{F}$ -statistic in the overall significance test can be written as:

$$\mathcal{F} = \frac{(SST - SSE) / K}{SSE / (N - K - 1)}. \quad (41)$$

■ **General notation:**

$$\mathbf{R} \times \beta = q, \quad (42)$$

where  $\mathbf{R}$  is the  $J \times (K + 1)$  matrix describing linear restriction and  $q$  is the vector of intercepts in each restriction.

■ **Example #1:** test of the overall significance of the regression model:

$$\mathbf{R} = \begin{bmatrix} 0 & 1 & 0 & \dots & 0 \\ 0 & 0 & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & 1 \end{bmatrix} \quad \text{and} \quad q = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix}$$

■ **Example #2:** the following restrictions

1.  $\beta_1 = \beta_3$
2.  $\beta_2 = \nu$
3.  $\beta_1 + \beta_4 = \gamma$ .

can be described as

$$\mathbf{R} = \begin{bmatrix} 0 & 1 & 0 & -1 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 \end{bmatrix} \quad \text{and} \quad q = \begin{bmatrix} 0 \\ \nu \\ \gamma \end{bmatrix}$$

- If a single restriction is considered both  $t$  and  $\mathcal{F}$  statistics can be used,
- The results will be identical.
- This is due to an exact relationship between  $t$ - and  $\mathcal{F}$ -distributions. The square of a  $t$  random variable with  $df$  degrees of freedom is an  $\mathcal{F}$  random variable with 1 degree of freedom in the numerator and  $df$  degrees of freedom in the denominator.

- In many cases we have information over and above the information contained in the sample observation.
- This **non-sample** information can be taken from e.g. economic theory.
- [Example] Production function. Consider the regression of logged output ( $y$ ) on logged capital ( $k$ ) and logged labor input ( $l$ ):

$$y = \beta_0 + \beta_1 k + \beta_2 l + \varepsilon. \quad (43)$$

The natural assumption to verify is constant return to scale (CRS). In this case:

$$\beta_1 + \beta_2 = 1. \quad (44)$$

## Delta method

- **Delta method** is the popular strategy for estimating variance for **nonlinear function of the parameters**.
- **Key assumption:** the  $g(\beta)$  is the nonlinear continuous function of the parameters.
- Taylor expansion around true value of the parameters, i.e.,  $\beta$ :

$$g(\hat{\beta}) = g(\beta) + \left( \frac{\partial g(\beta)}{\partial \beta} \right)' (\hat{\beta} - \beta) + o(\|\hat{\beta} - \beta\|), \quad (45)$$

where

$$\frac{\partial g(\beta)}{\partial \beta} = \left[ \frac{\partial g}{\partial \beta_1}, \frac{\partial g}{\partial \beta_K}, \dots, \frac{\partial g}{\partial \beta_K} \right]'. \quad (46)$$

- After manipulation

$$g(\hat{\beta}) - g(\beta) = \left( \frac{\partial g(\beta)}{\partial \beta} \right)' (\hat{\beta} - \beta) + o(\|\hat{\beta} - \beta\|), \quad (47)$$

and taking the variance

$$\text{var} (g(\hat{\beta}) - g(\beta)) = \left( \frac{\partial g(\beta)}{\partial \beta} \right)' \text{var} (\hat{\beta}) \left( \frac{\partial g(\beta)}{\partial \beta} \right). \quad (48)$$
